Rapid Color Guide # 355 Version 1 12/2011

Graphidaceae is the largest family of tropical lichens and, in its current circumscription, including the Thelotremae, Gomphillaceae, and Asterothyriaceae, possibly the largest family of lichenized fungi. Some 1800 species are currently accepted, 1500 of which belong to the core Graphidaceae (excluding subfamily Gomphilloideae). However, at the current rate of new species discoveries and considering the implementation of refined species concepts based on molecular evidence, it is predicted that the family actually comprises more than 2000 species in the core group alone.

Graphidaceae are characteristic elements of tropical forest ecosystems, being most diverse in lowland rain forests but also common in montane rain forest and extending into alpine vegetation, dry forest and thornbush, and Cerrado and savanna vegetation. Few species extend into temperate regions but several taxa are exclusive to these regions, such as the *Graphis scripta* complex. Graphidaceae are most commonly found on bark in shaded to exposed microsites, with each genus having its particular niche preferences. Most thelotremoid genera are excellent indicators of ecosystem health and can be used in standardized protocols to assess the conservation status of forest fragments in the tropics.

The current classification of Graphidaceae is very different from previous versions, distinguishing over 50 genera in the core group alone, whereas previous treatments recognized 12-14 genera. Growing evidence from molecular data continuously increases the number of clades recognized at the genus level, and the actual number of genera is predicted to be possibly close to 90. Some genera are now well-known and well-supported, but others such as *Chapsa*, *Fissurina*, and *Phaeographis*, require more studies to resolve their classification with confidence. A few genera have not yet been sequenced at all.
